Chlorpromazine is an effective antipsychotic drug. It is also a potent sedative, with doses which are commonly used in practice producing an immobile and unarousable state. This characteristic, its effectiveness against catatonia, and a very low side-effect profile suggest that chlorpromazine is an ideal agent for the treatment of catatonia. Its exact mechanisms of action are still being explored, although it is clear that the dopaminergic pathways are involved. Chlorpromazine is an effective hypnotic, and it is used widely in anaesthesia. In contrast to propofol and etomidate, the haemodynamic effects of chlorpromazine are not dose-related, suggesting that the characteristic sedation produced by chlorpromazine is not only due to anaesthesia but is a result of CNS depression. Side-effects are few and readily reversible on discontinuation of the drug. Etomidate is a new intravenous anaesthetic which is effective, smooth and safe, and is easier to use than chlorpromazine or other inhalational agents. Chlorpromazine produces cardiovascular stability, but it also produces hypothermia, and is associated with marked hypotension. Etomidate has few side-effects, it is not associated with hypotension, and produces no significant cardiovascular change. n to n' in general. Since $T(v)$ and $T(w)$ have the same lengths, one of the chains of v and the chain of w has exactly $j-1$ vertices. Let us show that $j \geq 2$. We may assume that v and w are separated by an edge e with $|v|=|w|=j$ and $e \in E(T(v)) \cap E(T(w))$. Suppose that
